Abstract

We analyze the structural determinants of two widely used measures of price discovery between multiple markets that trade closely related securities. Using a structural cointegration model, we show that both the information share (IS) and component share (CS) measures account for the relative avoidance of noise trading and liquidity shocks, but that only the IS can provide information on the relative informativeness of individual markets. In particular, the IS of one market is higher if it incorporates more new information and/or impounds less liquidity shocks. Use of the CS in conjunction with the IS can help sort out the confounding effects of the two types of shocks. Furthermore, we find that the IS only accounts for the immediate (one-period) responses of market prices to the news innovation, which implies that the IS estimates based on high sampling frequencies may be distorted by transitory frictions and may miss important price discovery dynamics.

1. Introduction

Price discovery is the dynamic process by which market prices incorporate new information, and is arguably one of the most important functions of financial markets. A

notable trend in financial markets is the trading of identical or closely related assets in multiple markets. The important issues related to price discovery are determining which market first incorporates new information about the underlying fundamental asset, and how the efficacy of price discovery depends on trading mechanisms, market liquidity, and the prevalence of asymmetric information.

There are two widely used measures of price discovery for multiple markets that share a common random walk efficient price. Hasbrouck (1995) focused on the variance of the efficient price innovation, and defined one market's information share (IS) as the proportion of the efficient price innovation variance attributable to that market. In contrast, Booth et al. (1999), Chu et al. (1999), and Harris et al. (2002), adopting the permanent-transitory decomposition technique in Gonzalo and Granger (1995), focused on the composition of the efficient price innovation and measure one market's contribution to price discovery by the component share (CS) of that market in forming the efficient price innovation.

Our analysis is motivated by the recent debate and discussion about the interpretation of IS and CS. As illustrated by the papers in the special issue on price discovery of the *Journal of Financial Markets* (Issue 3, 2002), there has been substantial confusion in the literature over what the IS and CS imply for price discovery measurement. The fundamental cause of this confusion is that both measures are defined in terms of the reduced form forecasting errors of individual markets from an empirical reduced form vector error correction (VEC) model. This view is emphasized by Lehmann (2002, p. 268), who stated: "This muddled state is unsurprising because the error correction model is a reduced form and the role of each market in price discovery depends on the parameters of the structural model".

In this paper, we directly address Lehmann's (2002) concern regarding the interpretation of the IS and CS by proposing a structural cointegration model for the price changes in multiple markets. Our model features two types of structural price shocks: a permanent news innovation to the common fundamental value and a transitory liquidity/noise trading shock. We show that the reduced form VEC forecasting errors are a mixture of these structural shocks, and this linkage allows us to analyze the dependency of the CS and IS on how individual markets respond to informational and non-informational shocks.

Our results show that both the IS and CS measures account for the relative avoidance of noise trading and liquidity shocks, but that only the IS can provide information on the relative informativeness of individual markets. In particular, the IS of one market is higher if it incorporates more new information and/or impounds less liquidity shocks. Use of the CS in conjunction with the IS can help sort out the confounding effects of the two types of shocks. Furthermore, we find that the IS only accounts for the immediate (one-period) responses of market prices to the news innovation. As a result, the IS estimates based on high sampling frequencies may be distorted by transitory frictions and misrepresent which market moves first in response to new information.

The rest of the paper is organized as follows. In Section 2, we review the derivation of the IS and CS from a reduced form cointegration model. In Section 3, we propose a structural cointegration model for the price changes in arbitrage-linked markets and show that our model is consistent with several stylized market microstructure models from the extant literature. We derive the structural analysis of the IS and CS in Section 4, and we illustrate our main results with analytical examples, simulation exercises, and an empirical

example from [Anand and Subrahmanyam \(2008\)](#). Our conclusions and suggestions for future research are presented in Section 5.

2. Reduced form price discovery cointegration model

Consider a single asset trading in two distinct markets.² Let $\mathbf{p}_t = (p_{1,t}, p_{2,t})'$ denote a 2×1 vector of (log) prices for the asset from the two markets. In a multiple-trading environment, these prices can be the trade prices or quotes from different trading venues. More generally, the prices can be an asset's cash market price and the price of its derivatives, or the observed price of an asset and its price synthetically constructed from other financial assets. As a result, these prices are closely linked by arbitrage. We assume each of these prices contains a random walk component, so that \mathbf{p}_t is integrated of order 1, or $I(1)$, and the price changes, $\Delta \mathbf{p}_t$, are integrated of order zero, or $I(0)$. We assume that $\Delta \mathbf{p}_t$ has a bivariate moving average (MA) or Wold representation:

$$\Delta \mathbf{p}_t = \Psi(L)\mathbf{e}_t = \mathbf{e}_t + \Psi_1\mathbf{e}_{t-1} + \Psi_2\mathbf{e}_{t-2} + \cdots, \quad (1)$$

where $\Psi(L) = \sum_{s=0}^{\infty} \Psi_s L^s$, $\Psi_0 = \mathbf{I}_2$, and \mathbf{e}_t is a 2×1 vector satisfying $E[\mathbf{e}_t] = \mathbf{0}$ and

$$E[\mathbf{e}_t \mathbf{e}_s'] = \begin{cases} \mathbf{0} & \text{if } t \neq s, \\ \Sigma & \text{otherwise.} \end{cases}$$

Because the prices in \mathbf{p}_t are for the same underlying asset, we assume that \mathbf{p}_t is cointegrated with known cointegrating vector $\beta = (1, -1)'$ so that $\beta' \mathbf{p}_t = p_{1,t} - p_{2,t}$ is $I(0)$ and \mathbf{p}_t has a VEC($K - 1$) model representation of the form

$$\Delta \mathbf{p}_t = \alpha(\beta' \mathbf{p}_{t-1} - \mu) + \sum_{k=1}^{K-1} \Gamma_k \Delta \mathbf{p}_{t-k} + \mathbf{e}_t, \quad (2)$$

where $\mu = E(\beta' \mathbf{p}_{t-1})$. The vector $\alpha \neq 0$ contains the error correction coefficients that measure each price's expected speed in eliminating the price difference.

The Beveridge–Nelson (BN) decomposition ([Beveridge and Nelson, 1981](#)) applied to (1) yields the levels relationship:

$$\mathbf{p}_t = \mathbf{p}_0 + \Psi(1) \sum_{j=1}^t \mathbf{e}_j + \mathbf{s}_t, \quad (3)$$

where $\Psi(1) = \sum_{k=0}^{\infty} \Psi_k$, $\mathbf{s}_t = (s_{1,t}, s_{2,t})' = \Psi^*(L)\mathbf{e}_t \sim I(0)$, and $\Psi_k^* = -\sum_{j=k+1}^{\infty} \Psi_j$, $k = 0, \dots, \infty$. The matrix $\Psi(1)$ contains the cumulative impacts of the innovation \mathbf{e}_t on all future price movements, and thus measures the long-run impact of \mathbf{e}_t on prices. As shown in [Hasbrouck \(1995\)](#), since $\beta' \Psi(1) = \mathbf{0}$ and $\beta = (1, -1)'$, the rows of $\Psi(1)$ are identical. As a result, the long-run impacts of an innovation \mathbf{e}_t on each of the prices are identical. Denote $\psi = (\psi_1, \psi_2)'$ as the common row vector of $\Psi(1)$ and define the permanent innovation:

$$\eta_t^P = \psi' \mathbf{e}_t = \psi_1 e_{1,t} + \psi_2 e_{2,t}. \quad (4)$$

²For simplicity, we focus on the two market case. Our analysis can be extended to the n market case. See [Yan and Zivot \(2006\)](#) for details.

We then rewrite (3) as the common stochastic trend representation suggested in [Stock and Watson \(1988\)](#):

$$\mathbf{p}_t = \mathbf{p}_0 + \mathbf{1}m_t + \mathbf{s}_t, \quad (5)$$

where $\mathbf{1} = (1, 1)'$, $m_t = m_{t-1} + \eta_t^P$, and $\mathbf{s}_t = \Psi^*(L)e_t$.

Eq. (5) shows that each of the cointegrated prices for the same underlying asset is composed of an unobservable, common fundamental full-information value m_t , a transitory pricing error $s_{i,t}$ in market i , and a constant. The common trend, defined as the efficient price in [Hasbrouck \(1995\)](#), evolves as a random walk driven by new information on the asset's future value captured by η_t^P . The pricing error $s_{i,t}$ captures any deviation of the price from its *current*, unobservable efficient price. It can arise from trading-related frictions, such as the bid–ask bounce and rounding effects, and lagged adjustment to new information. Finally, the remaining constant reflects any non-stochastic difference between the price and its efficient price, e.g., the average (half) bid–ask spread or the initial value. For simplicity, in what follows assume \mathbf{p}_0 is equal to the zero vector.³

2.1. Information share

[Hasbrouck \(1995\)](#) proposed a measure for one market's contribution to price discovery based on the share of the variance of η_t^P that is attributable to this market. If Σ is diagonal, then market i 's IS is defined as

$$IS_i = \frac{\psi_i^2 \sigma_i^2}{\psi' \Sigma \psi} = \frac{\psi_i^2 \sigma_i^2}{\psi_1^2 \sigma_1^2 + \psi_2^2 \sigma_2^2}, \quad i = 1, 2, \quad (6)$$

where ψ_i is the i th element of ψ , and σ_i^2 is the i th diagonal element in Σ . By construction, $IS_1 + IS_2 = 1$. From (6), it is clear that a low (high) information share for market i implies a small (large) reaction to the arrival of new information about fundamental value.

If Σ is non-diagonal, the IS measure has the problem of attributing the covariance terms to each market. [Hasbrouck \(1995\)](#) suggested to compute the Cholesky decomposition of Σ and measure the IS using the orthogonalized innovations. Let \mathbf{F} be a lower triangular matrix such that $\mathbf{F}\mathbf{F}' = \Sigma$. Then the IS for the i th market is

$$IS_i = \frac{([\psi' \mathbf{F}]_i)^2}{\psi' \Sigma \psi}, \quad (7)$$

where $[\psi' \mathbf{F}]_i$ is the i th element of the row matrix $\psi' \mathbf{F}$. The resulting IS depends on the ordering of price variables. In the bivariate case, the upper (lower) bound of the IS_i is obtained by computing the Cholesky factorization with the i th price ordered first (last). With n prices, [Hasbrouck \(2002\)](#) shows that one must examine all permutations of the variables.

For empirical implementations, [Hasbrouck \(1995, 2003\)](#) suggested sampling at very high frequencies to reduce the contemporaneous correlation in the reduced form residuals between markets that is created by time aggregation. The hope is that sampling at high frequencies exposes the sequential operation of markets so that the IS can accurately

³The common trends representation (5) is often used as the starting point for stylized models of price discovery (e.g., [Hasbrouck, 1995](#); [Harris et al., 2002](#)). However, interpretation problems immediately arise because the innovations η_t^P and \mathbf{s}_t may be correlated.

measure which market moves first in response to new information. Empirically, how often to sample prices to reduce residual correlation appears to be context specific. For example, in his study of determining the relative contribution to price discovery between the NYSE and regional exchanges, Hasbrouck (2003) used a sampling interval of 1 s, which produced a low contemporaneous residual correlation and a narrow range of information shares. Hendershott and Jones (2005) and Tse et al. (2005) also sampled at 1 s and found low residual correlations in their studies of price discovery on electronic exchanges. Grammig et al. (2005), who analyzed exchange rates along with equity quotes for three German firms trading on the NYSE and the XETRA, found little residual correlation when sampling at 10 s but substantial correlation when sampling at 1 min. Theissen (2002), in his study of price discovery in floor-based and electronic exchanges using data from the German stock market, found accurate IS measures with 1-min sampling but inaccurate measures using 5-min sampling. In contrast, Sapp (2002) studied price discovery in DM-\$US dealer quotes and found little difference in IS values using 30-s or 5-min sampling. Huang (2002), who studied the quote quality by ECN and NASDAQ dealers, used a 1-min sampling interval, which produced a substantial contemporaneous residual correlation and wide upper and lower bounds for the IS. In general, if the contemporaneous residual correlation is large, it is not unusual for the lower bound of one market's IS to be lower than the upper bound of another market's IS, making interpretation of the results difficult.

2.2. Component share

Booth et al. (1999), Chu et al. (1999), and Harris et al. (2002) proposed using the permanent-transitory (PT) component decomposition of Gonzalo and Granger (1995) to measure a market's contribution to price discovery. The Gonzalo–Granger PT decomposition of \mathbf{p}_t has the form

$$\mathbf{p}_t = \mathbf{A}_1 f_t + \mathbf{A}_2 \mathbf{z}_t, \quad (8)$$

where $f_t = \gamma' \mathbf{p}_t \sim I(1)$ is the permanent component, $\mathbf{z}_t \sim I(0)$ is the transitory component, and \mathbf{z}_t does not Granger cause f_t in the long run. Granger and Gonzalo defined $\gamma = (\alpha'_\perp \beta'_\perp)^{-1} \alpha'_\perp$, where α_\perp and β_\perp are 2×1 vectors such that $\alpha'_\perp \alpha = 0$ and $\beta'_\perp \beta = 0$. Since $\beta = (1, -1)'$, one choice for β_\perp is $\mathbf{1} = (1, 1)'$, implying $\gamma = (\alpha'_\perp \mathbf{1})^{-1} \alpha'_\perp$ so that the permanent component is a weighted average of observed prices with component weights $\gamma_i = \alpha_{\perp,i} / (\alpha_{\perp,1} + \alpha_{\perp,2})$ for $i = 1, 2$.⁴ As a result, Booth et al. (1999), Chu et al. (1999), and Harris et al. (2002) suggested measuring price discovery in market i using the component share (CS):

$$CS_i = \frac{\alpha_{\perp,i}}{\alpha_{\perp,1} + \alpha_{\perp,2}}, \quad i = 1, 2. \quad (9)$$

From (9), it is clear that a small (large) value of CS_i is directly related to a small (large) contribution of market i to the Granger–Gonzalo permanent component of prices f_t . However, as shown by Gonzalo and Granger (1995), the innovations to the permanent component f_t are generally not serially uncorrelated and so are different from the efficient price innovations η_t^P defined by (4). Therefore, the relationship between CS_i and IS_i is not

⁴In general, $\beta_\perp = c \cdot \mathbf{1}$, where $c \neq 0$. Therefore setting $\beta_\perp = \mathbf{1}$ imposes a particular normalization. However, the choice of normalization does not matter since the normalizing constant c cancels when forming CS_i .

immediately apparent. One advantage of the CS over the IS is its unique determination of a market's price discovery contribution.

Baillie et al. (2002) and De Jong (2002) showed that the vector of permanent component weights γ in the Granger–Gonzalo PT decomposition and the vector of long-run impact coefficients ψ that make up the efficient price innovation (4) are equal up to a scale factor. As a result, the CS measures can also be defined in terms of the elements of ψ as

$$CS_i = \frac{\psi_i}{\psi_1 + \psi_2}, \quad i = 1, 2. \quad (10)$$

The representation of CS in (10) shows that the IS is a variance-weighted version of CS when market innovations are uncorrelated.

Baillie et al. (2002) noted that since $\alpha_\perp' \alpha = 0$, (9) may also be expressed in terms of the elements of the error correction coefficient vector α :

$$CS_1 = \frac{\alpha_2}{\alpha_2 - \alpha_1}, \quad CS_2 = \frac{-\alpha_1}{\alpha_2 - \alpha_1}. \quad (11)$$

The representation (11) was originally derived by Schwarz and Szakmary (1994) using informal arguments. Interestingly, (11) shows that price discovery occurs entirely in market i if $\alpha_i = 0$; that is, if the contemporary price change in market i does not respond to the lagged disequilibrium error $\beta' p_{t-1} = p_{1t-1} - p_{2t-1}$.⁵ Booth et al. (1999) noted that $\beta' p_{t-1} = \alpha' A_2 z_{t-1}$ and argued that the error correction coefficients measure the way in which prices adjust to lagged differences in their transitory components. In this respect, CS_1 reflects how sensitive market 2 is, relative to market 1, to lagged transitory shocks and vice versa.

In the two market framework, the CS can be equivalently represented in terms of the elements of ψ , α , or α_\perp . The same is true for the IS. Martens (1998), Baillie et al. (2002), and Theissen (2002) provided formulas for the IS based on α or α_\perp and the elements of the Cholesky factorization of the reduced form VEC($K - 1$) covariance matrix.

3. Structural price discovery cointegration model

As emphasized by Lehmann (2002), because the IS and CS measures of price discovery are based on the residuals from a reduced form VEC model, their interpretation is not always clear. A clear interpretation of price discovery is only possible in a structural model (i.e., in a model in which the sources of shocks are identified). In this section, we propose a simple structural cointegration model for prices in arbitrated linked markets that identifies permanent and transitory shocks with minimal restrictions. Our model is motivated by the structural VAR models widely used in empirical macroeconomics (e.g., Bernanke, 1986; Blanchard and Quah, 1989; King et al., 1991). An excellent survey of these models, which we draw heavily from, is given in Levchenkova et al. (1999).

We start with the following structural moving average (SMA) representation for the price changes in multiple markets:

$$\Delta p_t = D(L)\eta_t = D_0\eta_t + D_1\eta_{t-1} + D_2\eta_{t-2} + \cdots, \quad (12)$$

⁵This interpretation of CS_i links price discovery in market i with the concept of weak exogeneity of prices for the cointegrating parameters in market i . See Zivot (2000) for a discussion of weak exogeneity in error correction models.

where $\mathbf{D}(L) = \sum_{k=0}^{\infty} \mathbf{D}_k L^k$, $\mathbf{D}_0 \neq \mathbf{I}_2$, and \mathbf{D}_0 is invertible. We assume that the number of structural shocks is equal to the number of observed prices, so that $\mathbf{D}(L)$ is invertible. Since \mathbf{p}_t is cointegrated, one shock is labeled permanent and the other is labeled transitory so that $\boldsymbol{\eta}_t = (\eta_t^P, \eta_t^T)'$. For identification, these structural shocks are assumed to be serially and mutually uncorrelated with diagonal covariance matrix $\text{diag}(\sigma_P^2, \sigma_T^2)$. In price discovery models, the permanent shock is the innovation to the fundamental value reflecting new information and economic considerations strongly suggest that this innovation should be uncorrelated with the transitory microstructure shocks. The matrix \mathbf{D}_0 contains the initial impacts of the structural shocks on $\Delta \mathbf{p}_t$, and defines the contemporaneous correlation structure of $\Delta \mathbf{p}_t$. Given the dichotomy into permanent and transitory shocks, the SMA model can be re-expressed equation-by-equation as

$$\begin{pmatrix} \Delta p_{1t} \\ \Delta p_{2t} \end{pmatrix} = \begin{pmatrix} d_1^P(L) & d_1^T(L) \\ d_2^P(L) & d_2^T(L) \end{pmatrix} \begin{pmatrix} \eta_t^P \\ \eta_t^T \end{pmatrix},$$

where $d_i^P(L)$ and $d_i^T(L)$ ($i = 1, 2$) are lag polynomials describing the dynamic responses to the permanent and transitory shocks, respectively.

The defining characteristic of η_t^P is that it has a one-to-one long-run effect on the expected price levels for each asset:

$$\lim_{k \rightarrow \infty} \frac{\partial E_t[\mathbf{p}_{t+k}]}{\partial \eta_t^P} = \lim_{k \rightarrow \infty} \sum_{l=0}^k \frac{\partial E_t[\Delta \mathbf{p}_{t+l}]}{\partial \eta_t^P} = \lim_{k \rightarrow \infty} \sum_{l=0}^k \mathbf{D}_l^P = \mathbf{D}^P(1) = \mathbf{1}, \quad (13)$$

where \mathbf{D}_k^P and $\mathbf{D}^P(1)$ are the first column of the dynamic multiplier matrix \mathbf{D}_k and the long-run impact matrix $\mathbf{D}(1)$ that corresponds to η_t^P , respectively. Eq. (13) is similar to the identifying condition for the permanent innovation used by [Gonzalo and Granger \(1995\)](#), which defines the permanent innovation as having a non-zero long-run effect of the level of variables. Economic considerations further restrict the long-run effect to be a vector of ones, since a one-unit increase in the fundamental value of one asset eventually cause the multiple market prices for the same asset to increase by one unit.

The defining characteristic of η_t^T is that it has no long-run effect on the expected price levels:

$$\lim_{k \rightarrow \infty} \frac{\partial E_t[\mathbf{p}_{t+k}]}{\partial \eta_t^T} = \lim_{k \rightarrow \infty} \sum_{l=0}^k \frac{\partial E_t[\Delta \mathbf{p}_{t+l}]}{\partial \eta_t^T} = \lim_{k \rightarrow \infty} \sum_{l=0}^k \mathbf{D}_l^T = \mathbf{D}^T(1) = \mathbf{0}, \quad (14)$$

where \mathbf{D}_k^T and $\mathbf{D}^T(1)$ are the second column of the dynamic multiplier matrix \mathbf{D}_k and the long-run impact matrix $\mathbf{D}(1)$ that corresponds to η_t^T , respectively. Hence, the long-run impact matrix of the structural innovations $\boldsymbol{\eta}_t$ has the form

$$\mathbf{D}(1) = \begin{bmatrix} 1 & 0 \\ 1 & 0 \end{bmatrix}. \quad (15)$$

Using (15), the BN decomposition of the SMA model in (12) is

$$\mathbf{p}_t = \mathbf{p}_0 + \mathbf{D}(1) \sum_{j=1}^t \boldsymbol{\eta}_j + \mathbf{s}_t = \mathbf{p}_0 + \mathbf{1}m_t + \mathbf{s}_t, \quad (16)$$

where $\mathbf{s}_t = \mathbf{D}^*(L)\eta_t \sim I(0)$, $\mathbf{D}_k^* = -\sum_{j=k+1}^{\infty} \mathbf{D}_j$, $k = 0, \dots, \infty$, and $m_t = m_{t-1} + \eta_t^P$. Eq. (16) shows that the SMA model implies the same common efficient price representation for the

multiple market prices as in the reduced form MA model (5), and the permanent innovation η_t^P in the SMA model is the same as the efficient price innovation defined in (4). The only difference is that the transitory pricing errors s_t in (16) are now driven by the structural innovations η_t . This implies that some of the pricing errors may be related to the arrival of new information, η_t^P , which includes, among others, the liquidity effect of information-related trading and the lagged price adjustment to new information.

Yan and Zivot (2006) showed that the parameters of the SMA model (12) can be uniquely identified from the parameters of the reduced form VEC model (2) using a modification of Gonzalo and Ng's (2001) permanent-transitory decomposition. The permanent shock is defined as (4) and the transitory shock η_t^T is defined from $\eta_t^T = \beta' e_t$ such that η_t^T is made orthogonal to η_t^P . This decomposition uniquely defines \mathbf{D}_0 in the bivariate case and the remaining SMA parameters can be recovered from the relationship $\mathbf{D}(L) = \Psi(L)\mathbf{D}_0$.

We emphasize that minimal assumptions have been imposed on the SMA model specification (12). Only the long run impacts of the structural innovations are specified. How the market prices respond overtime to new information and frictional factors is left unrestricted, and so the model is general enough to accommodate various complex market microstructure effects. In particular, no zero restrictions are placed on the contemporary impact matrix \mathbf{D}_0 to identify the structural shocks as would be done with a recursive causal ordering based on the Cholesky decomposition of the residual covariance matrix. As discussed by Ribba (1997) and Levchenkova et al. (1999), the Cholesky decomposition by itself does not identify the permanent and transitory shocks in a cointegrated VEC model because it does not guarantee a long-run impact matrix of the form (15). The additional restriction that one of the variables is weakly exogenous is also required.

3.1. Examples of structural models

To illustrate the SMA representation for a stylized market microstructure model, suppose the price $p_{i,t}$ in market i ($i = 1, 2$) follows:

$$p_{i,t} = m_t + s_{i,t}, \quad m_t = m_{t-1} + \eta_t^P, \quad s_{i,t} = b_{0,i}^P \eta_t^P + b_{0,i}^T \eta_t^T, \\ \eta_t = (\eta_t^P, \eta_t^T)' \sim i.i.d.N \left(\mathbf{0}, \begin{bmatrix} \sigma_P^2 & 0 \\ 0 & \sigma_T^2 \end{bmatrix} \right). \quad (17)$$

This model, which we call model 1, is similar to the structural model used by Lehmann (2002) to illustrate various aspects of price discovery measures. In (17), the pricing errors $s_{i,t}$ are partially due to the frictions by the information-related trading captured by $b_{0,i}^P$, and partially due to the frictions by the non-information-related trading captured by $b_{0,i}^T$. Since the trading direction, hitting the offer or taking the bid, is likely to be positively correlated with the nature of the new information in η_t^P , good or bad, $b_{0,1}^P$ and $b_{0,2}^P$ are both expected to be positive. Because η_t^T is the non-information-related innovation, it simply causes divergence between the two market prices so that $b_{0,1}^T$ and $b_{0,2}^T$ are expected to have opposite signs. Without loss of generality, it is assumed that $b_{0,1}^T > 0$ and $b_{0,2}^T < 0$.

The representation for $\Delta p_{i,t}$ ($i = 1, 2$) from (17) is

$$\Delta p_{i,t} = (1 + b_{0,i}^P) \eta_t^P + b_{0,i}^T \eta_t^T - b_{0,i}^P \eta_{t-1}^P - b_{0,i}^T \eta_{t-1}^T,$$

which implies a SMA representation of the form (12) with

$$\mathbf{D}_0 = \begin{pmatrix} 1 + b_{0,1}^P & b_{0,1}^T \\ 1 + b_{0,2}^P & b_{0,2}^T \end{pmatrix}, \quad \mathbf{D}_1 = \begin{pmatrix} -b_{0,1}^P & -b_{0,1}^T \\ -b_{0,2}^P & -b_{0,2}^T \end{pmatrix},$$

and $\mathbf{D}_k = \mathbf{0}$ for $k > 1$. Note that $\mathbf{D}(1) = \mathbf{D}_0 + \mathbf{D}_1$ satisfies the long-run restriction specified by (15). Also, if $b_{0,i}^P > 0$, then the initial impact of news is greater than the long-run impact.

As another example, consider an asymmetric structural model in which market 1 is a dominant market, and market 2 is a satellite market trading at the stale (lagged efficient) price:

$$p_{1,t} = m_t + s_{1,t}, \quad p_{2,t} = m_{t-1} + s_{2,t}, \quad m_t = m_{t-1} + \eta_t^P, \quad s_{i,t} = b_{0,i}^P \eta_t^P + b_{0,i}^T \eta_t^T, \quad i = 1, 2. \quad (18)$$

This model, which we call model 2, is similar to one used in [Hasbrouck \(1995\)](#). The price in market 1 is based on the current efficient price, whereas the price in market 2 is based on the one-period lagged or stale efficient price. Straightforward calculations give the SMA representation with

$$\mathbf{D}_0 = \begin{pmatrix} 1 + b_{0,1}^P & b_{0,1}^T \\ b_{0,2}^P & b_{0,2}^T \end{pmatrix}, \quad \mathbf{D}_1 = \begin{pmatrix} -b_{0,1}^P & -b_{0,1}^T \\ 1 - b_{0,2}^P & -b_{0,2}^T \end{pmatrix},$$

and $\mathbf{D}(1) = \mathbf{D}_0 + \mathbf{D}_1$ given by (15).

As a final example model with more complicated dynamics, which we call model 3, consider a partial price adjustment model similar to that used in [Amihud and Mendelson \(1987\)](#) and [Hasbrouck and Ho \(1987\)](#):

$$p_{it} = p_{it-1} + \delta_i(m_t - p_{it-1}) + b_{0,i}^T \eta_t^T, \quad m_t = m_{t-1} + \eta_t^P, \quad (19)$$

where $0 \leq \delta_i \leq 2$. Solving for Δp_{it} gives

$$\Delta p_{it} = d_i^P(L) \eta_t^P + d_i^T(L) \eta_t^T,$$

where $d_i^P(L) = [1 - (1 - \delta_i)L]^{-1} \delta_i$ and $d_i^T(L) = [1 - (1 - \delta_i)L]^{-1} (1 - L) b_{0,i}^T$. The SMA representation (12) is determined from the appropriate elements of the lag polynomials $d_i^P(L)$ and $d_i^T(L)$. In particular, the initial impact and long-run impact matrices are given by

$$\mathbf{D}_0 = \begin{pmatrix} d_1^P(0) & d_1^T(0) \\ d_2^P(0) & d_1^T(0) \end{pmatrix} = \begin{pmatrix} \delta_1 & b_{0,1}^T \\ \delta_2 & b_{0,2}^T \end{pmatrix}, \quad \mathbf{D}(1) = \begin{pmatrix} d_1^P(1) & d_1^T(1) \\ d_2^P(1) & d_1^T(1) \end{pmatrix} = \begin{pmatrix} 1 & 0 \\ 1 & 0 \end{pmatrix}.$$

[Amihud and Mendelson \(1987\)](#) used (19) with $b_{0,i}^T = 1$ to model the dynamics of price adjustment to fundamental value for a single security. [Hasbrouck and Ho \(1987\)](#) used this model with $b_{0,i}^T = 0$ to explain positive autocorrelations in stock returns. In the price discovery context, δ_i captures the speed of price discovery or information processing. Following a one-unit change to the efficient price, in each period market i 's price will move toward, or discover, the new efficient price at rate of δ_i . A value of δ_i closer to one implies a more efficient price discovery process. If $\delta_i = 1$ and $\eta_t^T = 0$, then new information is immediately incorporated and the market price will be equal to the efficient price. If $\delta_i > 1$, then overshooting of traders to new information occurs.

4. Structural interpretations of the IS and CS

Price discovery measures are supposed to distinguish which market prices incorporate new information regarding fundamental value more quickly and efficiently. For example, Hasbrouck (1995) interpreted the IS as measuring “who moves first in the process of price adjustment” and gave some simple examples in which the IS accurately reflects this interpretation. More recently, Baillie et al. (2002), Hasbrouck (2002) and Lehmann (2002) constructed simple microstructure models with various price discovery lead–lag structures and provided a comparative analysis of the IS and CS. In some examples, the IS and CS gave similar results and in other examples they differed considerably. However, the question of what the IS and CS actually measure in a structural dynamic model is complicated by the fact that these measures are defined in terms of the reduced form VEC innovations. Generally, reduced form innovations are best interpreted as forecasting errors, and are a mixture of various underlying structural innovations, which may include new information and non-information-related frictions. Forecasting errors by themselves do not have clear structural interpretations except in some special circumstances. Therefore, to examine what is actually measured by the IS and CS and to provide a clear linkage between them, a structural analysis of the two measures in terms of the underlying structural parameters and innovations is necessary.

We give a structural interpretation of the IS and CS using the structural cointegration model described in the previous section. From (1) and (12), the reduced-form forecasting errors, \mathbf{e}_t , are related to the structural innovations, $\boldsymbol{\eta}_t$, via the relation $\mathbf{e}_t = \mathbf{D}_0 \boldsymbol{\eta}_t$:

$$e_{1,t} = d_{0,1}^P \eta_t^P + d_{0,1}^T \eta_t^T, \quad e_{2,t} = d_{0,2}^P \eta_t^P + d_{0,2}^T \eta_t^T. \quad (20)$$

In (20), each of the forecasting errors can be attributed to the unobservable informational innovation η_t^P and frictional innovation η_t^T . The parameters $d_{0,i}^P$ and $d_{0,i}^T$ ($i = 1, 2$) are the contemporaneous responses of $p_{i,t}$ to the informational and frictional innovations, respectively.

Given that \mathbf{D}_0 is invertible, the structural errors can be expressed in terms of the reduced form errors via $\boldsymbol{\eta}_t = \mathbf{D}_0^{-1} \mathbf{e}_t$. Straightforward algebra then gives

$$\eta_t^P = \frac{d_{0,2}^T}{\Delta} e_{1,t} - \frac{d_{0,1}^T}{\Delta} e_{2,t}, \quad \eta_t^T = -\frac{d_{0,2}^P}{\Delta} e_{1,t} + \frac{d_{0,1}^P}{\Delta} e_{2,t}, \quad (21)$$

where $\Delta = |\mathbf{D}_0| = d_{0,1}^P d_{0,2}^T - d_{0,1}^T d_{0,2}^P$. Since the permanent innovation, η_t^P , in the SMA model (12) is the same as the efficient price innovation, $\eta_t^P = \psi_1 e_{1,t} + \psi_2 e_{2,t}$, defined from the reduced-form common trend model (4), the parameters ψ_1 and ψ_2 are linked to the initial impact structural parameters in \mathbf{D}_0 through

$$\psi_1 = \frac{d_{0,2}^T}{\Delta}, \quad \psi_2 = -\frac{d_{0,1}^T}{\Delta}. \quad (22)$$

Another way to derive (22) is to first note that $\mathbf{D}(L) = \boldsymbol{\Psi}(L) \mathbf{D}_0$ gives the relationship between the SMA polynomial matrix $\mathbf{D}(L)$ from (12) and the reduced form MA polynomial matrix $\boldsymbol{\Psi}(L)$ from (1). It follows that $\mathbf{D}(1) = [\mathbf{1} : \mathbf{0}] = \boldsymbol{\Psi}(1) \mathbf{D}_0 = \mathbf{1} \boldsymbol{\psi}' \mathbf{D}_0$. Therefore, the elements of $\boldsymbol{\psi}$ can be expressed in terms of the elements of \mathbf{D}_0 through the relation $\mathbf{D}(1) \mathbf{D}_0^{-1} = \mathbf{1} \boldsymbol{\psi}'$. Straightforward algebra confirms (22).

While ψ_1 and ψ_2 are weights on the respective market forecasting errors used to define the efficient price innovation in (4) and used in the IS and CS to measure each market's

contribution to discover new information, Eq. (22) reveals that they are, in fact, proportional to the markets' contemporaneous responses to the structural frictional innovation. This seemingly paradoxical result can be explained by the mixture nature of the forecasting errors (i.e., they contain both informational and frictional innovations) and the fact that the long-run structural impact parameters in $\mathbf{D}(1)$ are normalized to unity by assumption. When Eq. (4) extracts the permanent innovation η_t^P from the reduced-form forecasting errors \mathbf{e}_t , the transitory innovation η_t^T must be purged. It can be shown that it is the requirement to remove the frictional innovation that leads to the result in (22).

4.1. Component share

We are now ready to consider the structural interpretation of the CS. Using (22), the structural representation of the CS for markets 1 and 2 is

$$CS_1 = \frac{d_{0,2}^T}{d_{0,2}^T - d_{0,1}^T}, \quad CS_2 = \frac{-d_{0,1}^T}{d_{0,2}^T - d_{0,1}^T}, \quad (23)$$

provided $d_{0,2}^T \neq d_{0,1}^T$.⁶ Surprisingly, (23) shows that the CS only involves the structural parameters governing the price responses to the frictional innovation. Instead of measuring the relative strength of how a given market price responds to new information,⁷ the CS measures the relative response to contemporaneous transitory frictions. In particular, $|CS_1/CS_2| = |d_{0,2}^T/d_{0,1}^T|$ so that CS_1 will be higher than CS_2 if market 2 responds more strongly to the transitory shock than market 1. Moreover, it follows from (23) that $CS_1 = 1$ only if $d_{0,1}^T = 0$ and vice versa. The structural representation of the CS in (23) is similar to reduced-form representation (11) based on the error correction coefficients. In fact, (11) and (23) imply that the error correction coefficients α_i are proportional to the contemporaneous transitory impact parameters $d_{0,i}^T$. However, the interpretation is slightly different. In the reduced-form representation (11), CS_1 measures the relative *lagged* response of market 2 to the Granger–Gonzalo transitory components of the disequilibrium error $\beta' \mathbf{p}_t$.

To illustrate the structural representation of the CS, consider the three stylized microstructure models presented in Section 3.1. Since the initial impacts of the transitory shocks are specified in the same way across the three models, application of (23) gives

$$CS_1 = \frac{b_{0,2}^T}{b_{0,2}^T - b_{0,1}^T}, \quad CS_2 = \frac{-b_{0,1}^T}{b_{0,2}^T - b_{0,1}^T} \quad (24)$$

for all three models. As a further illustration, Table 1 gives two parameterizations of model 1 given by (17). The first row of the table gives the SMA representation of (17) with $b_{0,1}^P = b_{0,2}^P = 0$, $b_{0,1}^T = 0$ and $b_{0,2}^T = \varepsilon \neq 0$. In this case, both markets fully incorporate the impact of new information when it arrives. Market 1 does not respond to the transitory

⁶Notice that the CS is not defined if $d_{0,2}^T = d_{0,1}^T$. In this case, (22) shows that $\psi' \mathbf{1} = \psi_1 + \psi_2 = 0$ so that $\psi = \alpha_\perp$ is orthogonal to $\mathbf{1}$. Since $\beta = (1, -1)'$ is also orthogonal to $\mathbf{1}$, it follows that $\alpha_\perp' \beta_\perp = 0$, which implies that there is no common permanent component in the vector of prices. In other words, $\beta = (1, -1)'$ cannot be a cointegrating vector if $d_{0,2}^T = d_{0,1}^T$. Also, if both markets react in the same way to the permanent and transitory shocks, then \mathbf{D}_0 is not invertible and these shocks cannot be separately identified from the data.

⁷Lehmann (2002) reaches the same conclusion based on the observation that the CS only involves the long-run impacts of the reduced-form innovations on the prices.

Table 1
CS and IS from stylized structural models.

\mathbf{D}_0	\mathbf{D}_1	CS ₁	CS ₂	IS ₁	IS ₂
$\begin{pmatrix} 1 & 0 \\ 1 & \varepsilon \end{pmatrix}$	$\begin{pmatrix} 0 & 0 \\ 0 & -\varepsilon \end{pmatrix}$	1	0	1	0
$\begin{pmatrix} \varepsilon & \delta \\ 1 & -\delta \end{pmatrix}$	$\begin{pmatrix} 1-\varepsilon & -\delta \\ 0 & \delta \end{pmatrix}$	0.5	0.5	$\frac{\varepsilon}{1+\varepsilon}$	$\frac{1}{1+\varepsilon}$

This table reports the analytical results of the information share (IS) and component share (CS) based on two parameterizations of the following 2-market model:

$$p_{i,t} = m_t + s_{i,t}, m_t = m_{t-1} + \eta_t^P, s_{i,t} = b_{0,i}^P \eta_t^P + b_{0,i}^T \eta_t^T,$$

where the structural errors $\eta_t = (\eta_t^P, \eta_t^T)$ are normally distributed with zero means, diagonal covariance matrix $\text{diag}(\sigma_P^2, \sigma_T^2)$, and are mutually uncorrelated at all leads and lags. \mathbf{D}_0 and \mathbf{D}_1 correspond to the price responses to innovations η_t at time t (contemporaneous) and $t + 1$ (one period later). CS _{i} and IS _{i} are the CS and IS for market i , respectively. The first row of the table is based on $b_{0,1}^P = b_{0,2}^P = 0$, $b_{0,1}^T = 0$ and $b_{0,2}^T = \varepsilon \neq 0$. The second row is based on $b_{0,1}^P = \varepsilon - 1$, $b_{0,2}^P = 0$, and $b_{0,1}^T = -b_{0,2}^T = \delta \neq 0$. The IS values are based on the zero covariance restriction on the reduced form errors.

shock at all and its price is equal to the efficient price, whereas ε captures the contemporaneous impact of the transitory shock on market 2. From (24), we see that CS₁ = 1 and CS₂ = 0. This result holds even if ε is arbitrarily close to zero. The second row of Table 1 gives the SMA representation with $b_{0,1}^P = \varepsilon - 1$, $b_{0,2}^P = 0$, and $b_{0,1}^T = -b_{0,2}^T = \delta \neq 0$. In this case, market 1 only incorporates the fraction ε of the permanent shock in the initial period whereas market 2 fully incorporates the shock. Additionally, both markets respond equally (in absolute value) to the transitory shock. Using (24), it follows that CS₁ = CS₂ = 0.5 regardless of the value of ε . These two examples illustrate situations in which the CS can give highly misleading information regarding the price discovery efficiency of a market.

4.2. Information share

Now consider the structural interpretation of the IS. A full structural analysis of the IS is complicated by covariance structure of the reduced form forecasting errors. When the reduced form innovations, \mathbf{e}_t , are uncorrelated, the IS is supposed to give unambiguous results. This special case also allows for a clear structural interpretation of the IS using the structural cointegration model.

Using (20) and $\text{cov}(\eta_t^P, \eta_t^T) = 0$, it follows that $\text{var}(e_{1t}) = (d_{0,1}^P)^2 \sigma_P^2 + (d_{0,1}^T)^2 \sigma_T^2$, $\text{var}(e_{2t}) = (d_{0,2}^P)^2 \sigma_P^2 + (d_{0,2}^T)^2 \sigma_T^2$, and $\text{cov}(e_{1t}, e_{2t}) = d_{0,1}^P d_{0,2}^P \sigma_P^2 + d_{0,1}^T d_{0,2}^T \sigma_T^2$. As a result, there are three cases in which $\text{cov}(e_{1t}, e_{2t}) = 0$ and an unambiguous structural interpretation of IS can be made.

The first case occurs when $d_{0,2}^P = d_{0,1}^T = 0$ and $d_{0,1}^P d_{0,2}^T \neq 0$ so that $e_{1t} = d_{0,1}^P \eta_t^P$ and $e_{2t} = d_{0,2}^T \eta_t^T$. Here, market 1 only responds contemporaneously to the permanent shock and market 2 only responds to the transitory shock. This case has the structure of the stale price model (18). Using (6) and (22), it follows that IS₁ = 1 so that the IS correctly captures “who moves first” with respect to new information. Since $d_{0,1}^T = 0$, it follows from (23) that CS₁ = 1 and so the IS and CS give the same results. The second case in which

$\text{cov}(e_{1t}, e_{2t}) = 0$ occurs is when $d_{0,1}^P = d_{0,2}^T = 0$ and $d_{0,2}^P d_{0,1}^T \neq 0$, so that only market 2 responds contemporaneously to the permanent shock. Here, $\text{IS}_2 = \text{CS}_2 = 1$ and these measures again correctly capture “who moves first.” These two cases correspond to Hasbrouck’s (1995) explanation that sampling at high frequencies exposes the sequential operation of markets so that the IS can accurately measure which market moves first in response to new information.

The third case in which $\text{cov}(e_{1t}, e_{2t}) = 0$ occurs is when

$$\frac{\sigma_T^2}{\sigma_P^2} = \frac{d_{0,1}^P d_{0,2}^P}{-d_{0,1}^T d_{0,2}^T}, \quad (25)$$

and all elements of \mathbf{D}_0 are non-zero such that $|\mathbf{D}_0| \neq 0$. Using (6), (22), and (25), it follows after some algebra that

$$\text{IS}_1 = \frac{d_{0,1}^P d_{0,2}^T}{\Delta}, \quad \text{IS}_2 = \frac{-d_{0,1}^T d_{0,2}^P}{\Delta}, \quad (26)$$

where $\Delta = d_{0,1}^P d_{0,2}^T - d_{0,1}^T d_{0,2}^P$. In this case, the structural representation of the IS consists of contemporaneous responses to both permanent and transitory shocks. This result is in contrast to Hasbrouck’s claim that the IS effectively ignores transient price disturbances (Hasbrouck, 1995, p. 1184). The expressions for the IS in (26) reduce to the expressions for the CS in (23) if $d_{1,0}^P = d_{2,0}^P$. In this case, both the IS and CS only depend on the contemporaneous impacts of the transitory shocks.

Compared with the structural representation of the CS in (23), the IS representation with uncorrelated residuals is more appropriate for measuring price discovery because the IS for one market contains that market’s response to new information. However, the presence of the frictional innovation’s contemporaneous impact in (26) implies that the IS cannot always be interpreted without ambiguity. Specifically, a high IS value for one market due to the market’s strong response to new information cannot be distinguished from a high IS value due to another market’s strong response to frictions. That is, a high value for IS_1 can be caused by a high value for $d_{0,1}^P$, a high value for $d_{0,2}^T$, or high values for both parameters. Additional information from the CS, however, may help to remove some of the ambiguity associated with the IS. Because the CS purely measures one market’s response to transitory frictions relative to another market, the relative impact of the permanent shocks can be measured using

$$\left| \frac{\text{IS}_1 \text{CS}_2}{\text{IS}_2 \text{CS}_1} \right| = \left| \frac{d_{0,1}^P}{d_{0,2}^P} \right|. \quad (27)$$

For example, a high IS accompanied by a low CS provides evidence that a market has a relatively strong response to the informational innovation. A high IS together with a high CS would suggest otherwise.

Table 2 gives the IS values for the three stylized microstructure models presented in Section 3.1 under the assumption that the reduced form errors are uncorrelated based on (25). In general, the IS cannot be interpreted without ambiguity for the three models. For example, in the stale price model (18), IS_1 could be small if $|b_{0,1}^T|$ is very large relative to $|b_{0,2}^T|$. This situation can be uncovered by examining (27). Similarly, in the partial adjustment model (19), the market with the most efficient price discovery is the one in

Table 2
IS from stylized structural models.

Model	IS ₁	IS ₂	Δ
1	$\Delta^{-1}(1 + b_{0,1}^P)b_{0,2}^T$	$-\Delta^{-1}(1 + b_{0,2}^P)b_{0,1}^T$	$(1 + b_{0,1}^P)b_{0,2}^T - (1 + b_{0,2}^P)b_{0,1}^T$
2	$\Delta^{-1}(1 + b_{0,1}^P)b_{0,2}^T$	$-\Delta^{-1}b_{0,2}^Pb_{0,1}^T$	$(1 + b_{0,1}^P)b_{0,2}^T - b_{0,2}^Pb_{0,1}^T$
3	$\Delta^{-1}\delta_1b_{0,2}^T$	$-\Delta^{-1}\delta_2b_{0,1}^T$	$\delta_1b_{0,2}^T - \delta_2b_{0,1}^T$

This table reports the analytical results of the information share (IS) based on the three stylized microstructure models presented in Section 3.1 under the zero covariance restriction (27).

which δ_i is closest to 1. However, the IS measures are confounded by the transitory impact parameters. Application of (27) gives the relative impact of the permanent shocks δ_1/δ_2 .

As a final illustration of the structural interpretation of the IS, consider the parameterizations of the stylized model (17) given in Table 1 under the zero covariance restriction (25). For the first parameterization, since the initial impacts to the permanent shocks are the same, the IS values are the same as the CS values and attribute all price discovery to the first market. For the second parameterization, $IS_1 = \varepsilon/(1 + \varepsilon)$, $IS_2 = 1/(1 + \varepsilon)$ and the ratio (27) is equal to ε . If $\varepsilon \approx 0$, then market 1 does not have an immediate impact from the permanent shock and $IS_1 \approx 0$ and $IS_2 \approx 1$. In contrast, if $\varepsilon \approx 1$, then markets 1 and 2 react in the same way to the permanent shocks and $IS_1 \approx IS_2 \approx 0.5$.

4.3. Simulation example

To illustrate the empirical relevance of the analytical results for the IS and CS in (23) and (26), we compare the estimated CS and IS to their true analytical values using simulated data from two parameterizations of the stylized partial adjustment microstructure model (19). For the first parameterization, we set $\delta_1 = 0.8$, $\delta_2 = 0.2$, $b_{0,1}^T = 0.5$, and $b_{0,2}^T = -0.5$. Market 1 has a greater speed of price discovery than market 2, and both markets respond equally, in absolute value, to the transitory shocks. Using (25) with $\sigma_P^2 = 1$ and $\sigma_T^2 = 0.64$ removes the correlation between the reduced form-residuals. From (23) and (26), the analytic values for the CS and IS for market 1 are $CS_1 = 0.5$ and $IS_1 = 0.8$, respectively. From (22), the analytic value for $\psi = \alpha_\perp$ is $(1, 1)'$, which implies that $\alpha = (\alpha_1, -\alpha_1)'$. For the second parameterization, we set $\delta_1 = 0.8$, $\delta_2 = 0.2$, $b_{0,1}^T = 0.9$, $b_{0,2}^T = -0.1$, $\sigma_P^2 = 1$, and $\sigma_T^2 = 1.778$. Here, market 1 responds more strongly to the contemporaneous transitory shock than market 2. The corresponding values for the CS and IS for market 1 are $CS_1 = 0.1$ and $IS_1 = 0.308$, respectively, and $\psi = (0.385, 3.462)'$. Here, the low values of CS_1 and IS_1 indicate that market 1 responds more strongly to the contemporaneous transitory shock than market 2 and not that market 2 responds more strongly to the contemporaneous permanent shock.

Based on the specified parameters, we generate 1000 artificial samples of size 100, 250, 500, 750, 1000, 5000, and 10000 observations from the bivariate price system (19) assuming normally distributed errors. To mimic what a researcher would do in practice, we fit the reduced form VEC($K - 1$) model (2) using ordinary least squares with the lag order of the system determined by minimizing the Bayesian information criterion (BIC). We then estimate the CS from (10) and the IS from (7) using the parameters of the fitted VEC($K - 1$) model. To estimate $\Psi(1)$, we use the Johansen factorization $\Psi(1) = \beta_\perp(\alpha_\perp' \Gamma(1)\beta_\perp)^{-1}\alpha_\perp'$,

where $\Gamma(1) = \mathbf{I}_2 - \sum_{j=1}^{K-1} \Gamma_j$, and then estimate ψ as the common row of the estimate of $\Psi(1)$. To estimate α_\perp and β_\perp up to a scale factor, we use the normalized eigenvectors associated with the matrices $\alpha\alpha'$ and $\beta\beta'$, respectively.

The results of the experiments are summarized in Tables 3–5. For each experiment, the tables report estimates (averaged over the 1000 simulations) of some of the $\text{VEC}(K-1)$ parameters ($\alpha_1, \alpha_2, K-1, \psi_1, \psi_2, \rho = \text{cov}(e_{1t}, e_{2t})$), as well as the price discovery measures for market 1 ($\text{IS}_{L,1}$, $\text{IS}_{U,1}$, and CS_1) for various sample sizes. The results in Tables 3 and 4 show that the IS and CS are very accurately estimated for samples larger than 500 observations. For small sample sizes, the IS and CS tend to be underestimated with high variability across the simulations. Table 5 reports the results from an experiment in which 500 observations are simulated from the second parameterization of the partial adjustment model but the $\text{VEC}(K-1)$ model (2) is estimated using data sampled at every m th observation for $m = 1, 2, \dots, 5$. This experiment is designed to illustrate the impact of high frequency transitory microstructure effects on the IS and CS when these measures are estimated using data sampled at different frequencies. At coarse sampling frequencies (e.g., $m = 5$), there are severe biases in the $\text{VEC}(K-1)$ parameter estimates, and the estimated

This table reports the estimates of the information share (IS) and component share (CS) from the price data simulated from the following partial adjustment model:

$$p_{i,t} = p_{i,t-1} + \delta_i(m_t - p_{i,t-1}) + b_{0,i}^T \eta_i^T, m_t = m_{t-1} + \eta_i^P,$$

where the structural errors $\eta_i = (\eta_i^P, \eta_i^T)'$ are normally distributed with zero means, and diagonal covariance matrix $\text{diag}(\sigma_P^2, \sigma_T^2)$, and are mutually uncorrelated at all leads and lags. The simulation parameterization is $\delta_1 = 0.8, \delta_2 = 0.2, b_{0,1}^T = 0.5, b_{0,2}^T = -0.5, \sigma_P^2 = 1$, and $\sigma_T^2 = 0.64$. For each sample, the VEC model (2) is fitted with the BIC optimal lag length and the CS and IS values are computed using (11) and (7). The numbers in each column represent averages over the simulations with Monte Carlo standard deviations in parentheses. Total simulations = 1000.

Table 4
CS and IS estimates from simulated prices.

This table reports the estimates of the information share (IS) and component share (CS) from the price data simulated from the following partial adjustment model:

$$p_{i,t} = p_{i,t-1} + \delta_i(m_t - p_{i,t-1}) + b_{0,i}^T \eta_t^T, m_t = m_{t-1} + \eta_t^P,$$

where the structural errors $\eta_t = (\eta_t^P, \eta_t^T)'$ are normally distributed with zero means, and diagonal covariance matrix $diag(\sigma_P^2, \sigma_T^2)$, and are mutually uncorrelated at all leads and lags. The simulation parameterization is $\delta_1 = 0.8, \delta_2 = 0.2, b_{0,1}^T = 0.9, b_{0,2}^T = -0.1, \sigma_P^2 = 1$, and $\sigma_T^2 = 1.778$. For each sample, the VEC model (2) is fitted with the BIC optimal lag length and the CS and IS values are computed using (11) and (7). The numbers in each column represent averages of the estimates over the simulations with Monte Carlo standard deviations in parentheses. Total simulations = 1000.

residual correlation is large and positive. As a result, $IS_{L,1}$ is close to zero and $IS_{U,1}$ is close to one so that these estimates are not informative about price discovery. Interestingly, the CS estimates are not as badly biased as the IS estimates. As the sampling frequency approaches the true frequency ($m = 1$), the $VEC(K - 1)$ estimates become more accurate and the estimated residual correlation approaches zero. However, the IS estimates are still influenced by the contemporaneous transitory shock. The low values of IS_1 and CS_1 indicate that market 1 responds more strongly to the contemporaneous transitory shock than market 2 and not that market 2 responds more strongly to the contemporaneous permanent shock.

4.4. Empirical example

An empirical example showing the practical relevance of the simulation experiment and our structural interpretation of the IS is given in [Anand and Subrahmanyam \(2008\)](#), and is discussed in detail in [Harris et al. \(2008\)](#). For the electronic Toronto Stock Exchange, Anand and Subrahmanyam find a higher IS for the execution channel (channel 1) in which

Table 5

CS and IS estimates from simulated prices sampled at different frequencies.

True value		Sampling increment, m				
		1	2	3	4	5
α_1		−0.558 (0.047)	−0.719 (0.093)	−0.761 (0.139)	−0.777 (0.188)	−0.753 (0.232)

This table reports the estimates of the information share (IS) and component share (CS) from the price data simulated from the following partial adjustment model:

$$p_{i,t} = p_{i,t-1} + \delta_i(m_t - p_{i,t-1}) + b_{0,i}^T \eta_t^T, m_t = m_{t-1} + \eta_t^P,$$

where the structural errors $\eta_t = (\eta_t^P, \eta_t^T)'$ are normally distributed with zero means, and diagonal covariance matrix $diag(\sigma_P^2, \sigma_T^2)$, and are mutually uncorrelated at all leads and lags. The simulation parameterization is $\delta_1 = 0.8, \delta_2 = 0.2, b_{0,1}^T = 0.9, b_{0,2}^T = -0.1, \sigma_P^2 = 1$, and $\sigma_T^2 = 1.778$. For each sample, the VEC model is fitted to data sampled at increments $m = 1, 2, \dots, 5$ with the BIC optimal lag length and the CS and IS values are computed using (11) and (7). Then numbers in each column represent averages of the estimates over the simulations with Monte Carlo standard deviations in parentheses. Total simulations = 1000.

intermediaries (brokers and specialists) trade for their own accounts than for the execution channel (channel 2) in which they trade for their clients accounts but can find no direct evidence that intermediaries are better informed than their clients. Based on (26), Harris et al. (2008) argued that one should conclude that IS_1 is high not because channel 1 impounds information shocks better than channel 2 but that the clients in channel 2 respond relatively more strongly to transitory noise or order imbalances that they interpret as permanent shocks. That is, $IS_1 > IS_2$ not because $d_{0,1}^P > d_{0,2}^P$ but because $d_{0,2}^T > d_{0,1}^T$.

5. Conclusions

Using a structural cointegration model, we investigate the structural determinants of the information share (IS) and the component share (CS)—two widely used price discovery measures. We find that the two measures alone cannot distinguish the price discovery dynamics between markets. In particular, the CS does not reflect a market's price responses to new information at all, and the IS cannot be interpreted unambiguously even when the cross-market innovations are uncorrelated. We show how the IS and CS can be

used together to disentangle the impacts of permanent and transitory shocks. In addition, we show that the IS and CS are essentially static measures since they only account for contemporaneous price responses to the underlying structural innovations.

In a two market framework, our structural cointegration model can be used to define unambiguous measures of price discovery that capture the full dynamic process of how new information impacts prices. This is possible because the underlying structural shocks can be uniquely identified using a modification of the permanent-transitory decomposition of Gonzalo and Ng (2001). These new dynamic measures of price discovery are described and analyzed in detail in Yan and Zivot (2006).
